```

## Hypotheses

### Predator Satiation

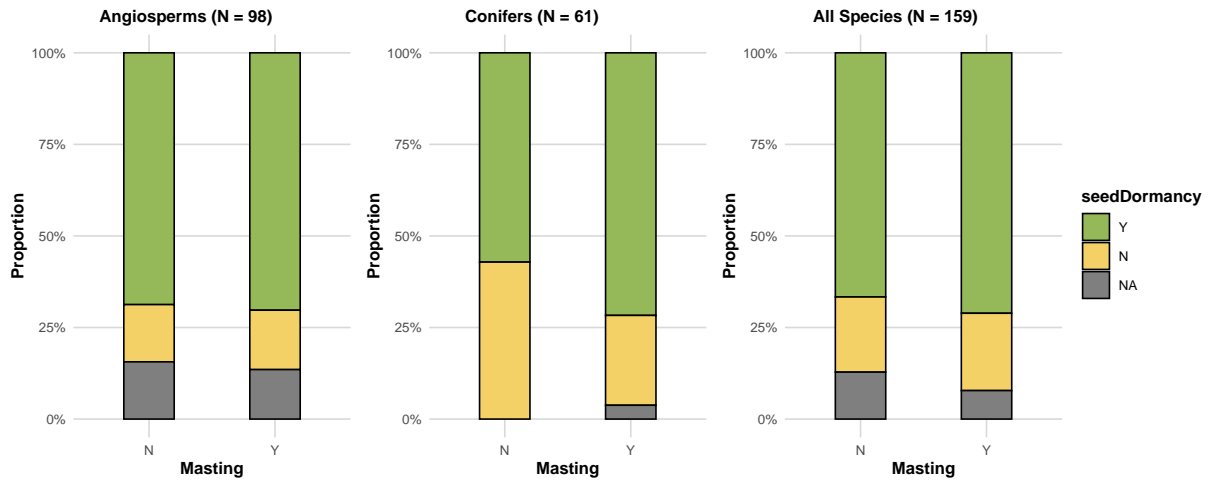

- Dispersal mode: Animal-dispersed species may be more likely to mast, or the mechanisms behind masting could differ depending on dispersal mode.

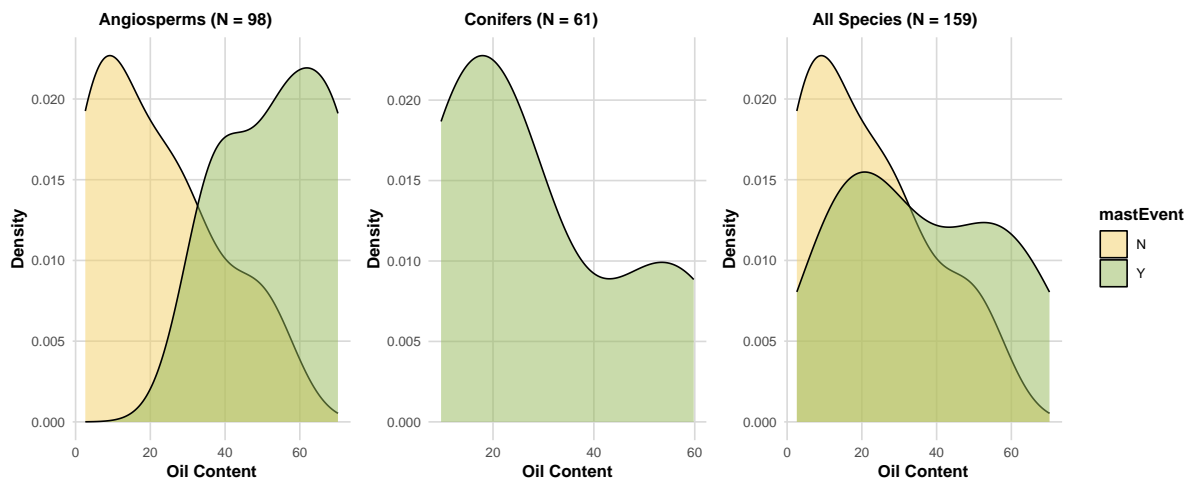

- **Seed size:** Among animal-dispersed species, larger-seeded species might be more prone to masting.

- **Seed dormancy:** Species with dormant seeds are expected to be more likely to mast.

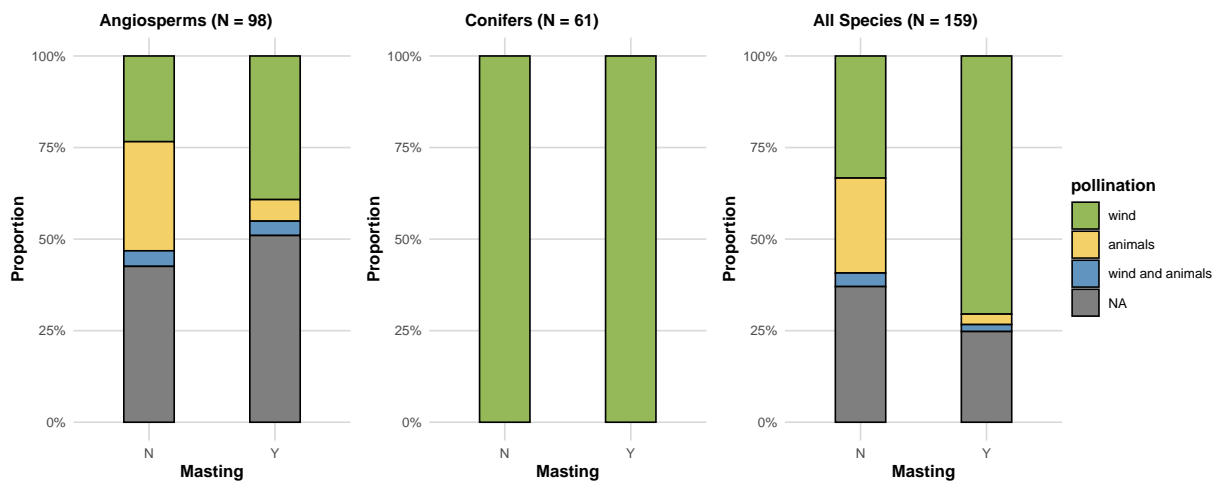

- **Nutrient content:** Species with more nutritious seeds may be more likely to mast.

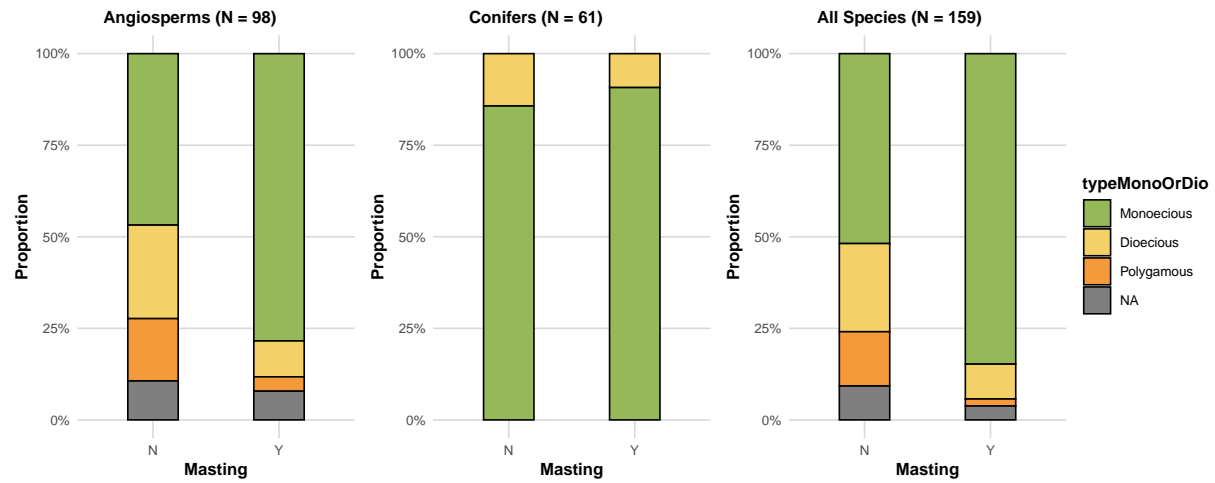

## Pollination Coupling

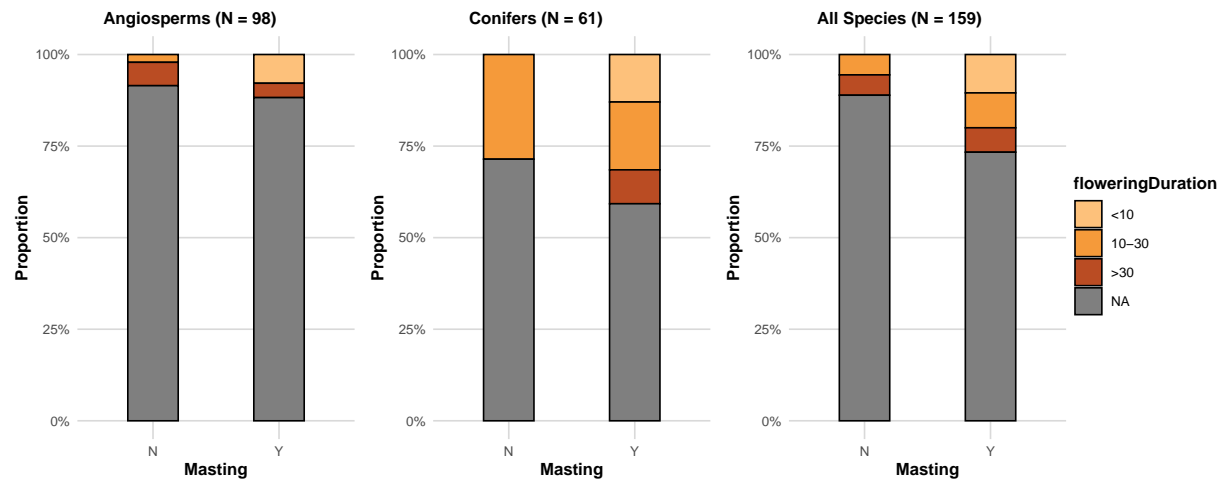

- Wind-pollinated species are expected to mast more frequently.

- Monoecious species may be more likely to mast.

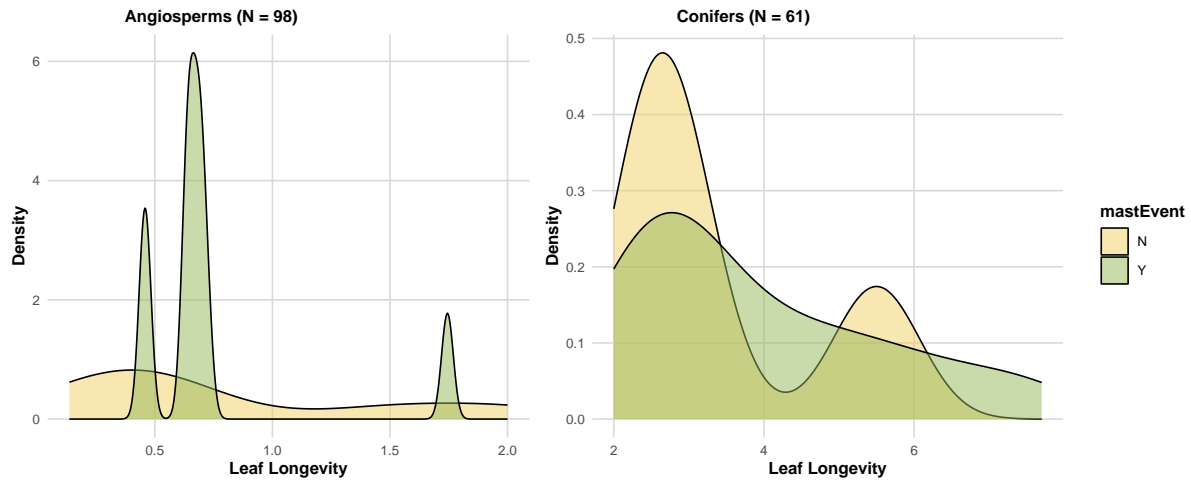

- Species with longer flowering periods may be more likely to mast.

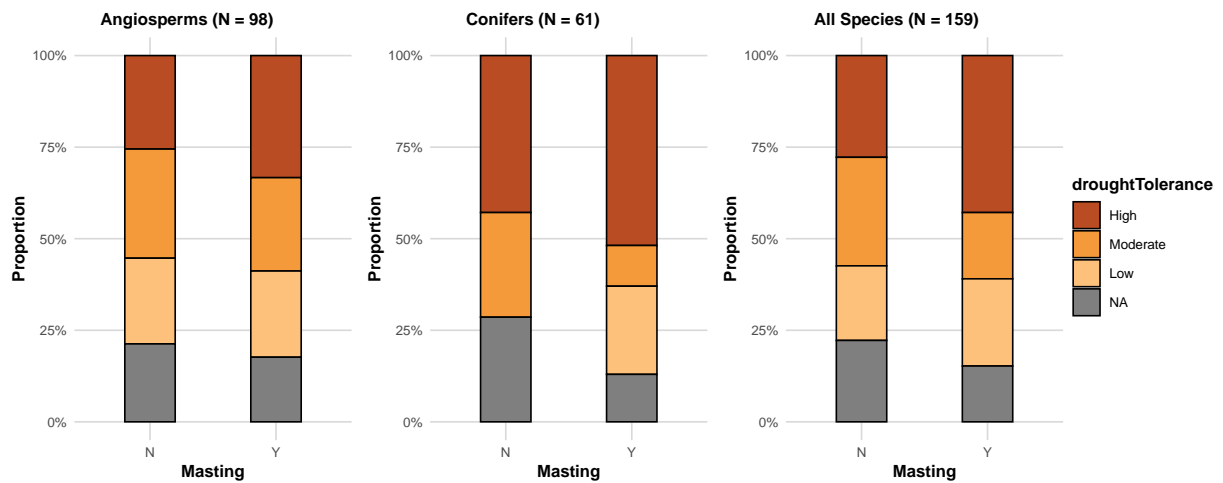

# Resource Matching

- Leaf longevity: Species with long-lived leaves are expected to mast more frequently.

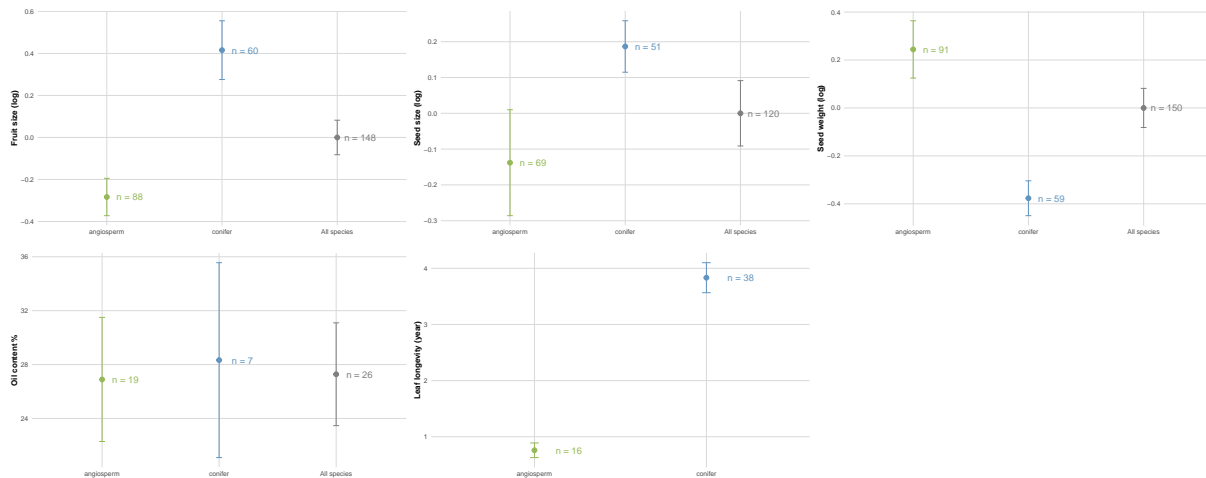

- Drought tolerance: May go either way — tolerant species can accumulate resources; intolerant species respond to resource fluctuations.

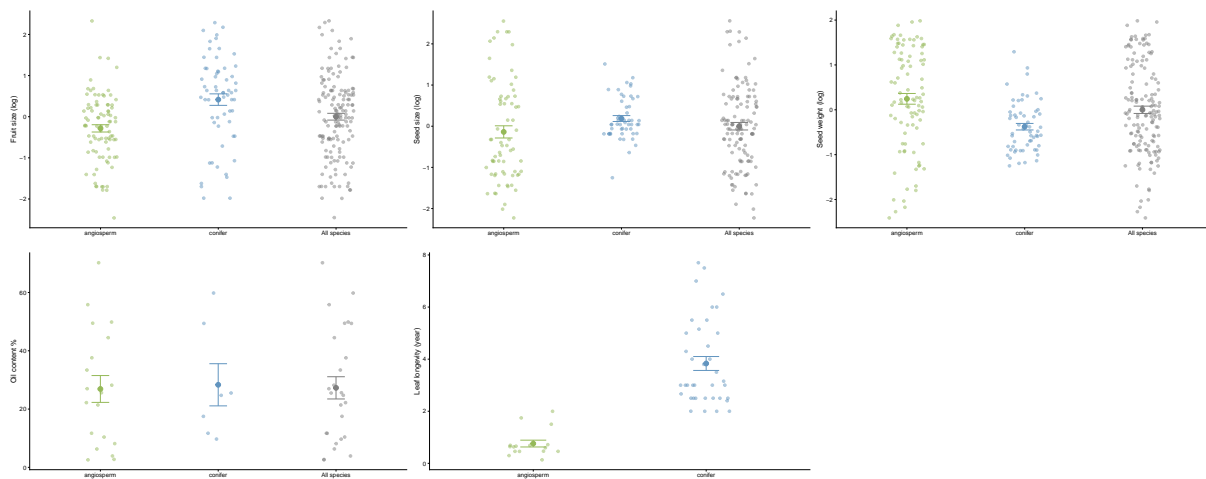

## Data visualization

I calculated the mean and standard errors for the continuous traits in the raw dataset, with number of the data.

Here's the version of raw data scattering on the plot

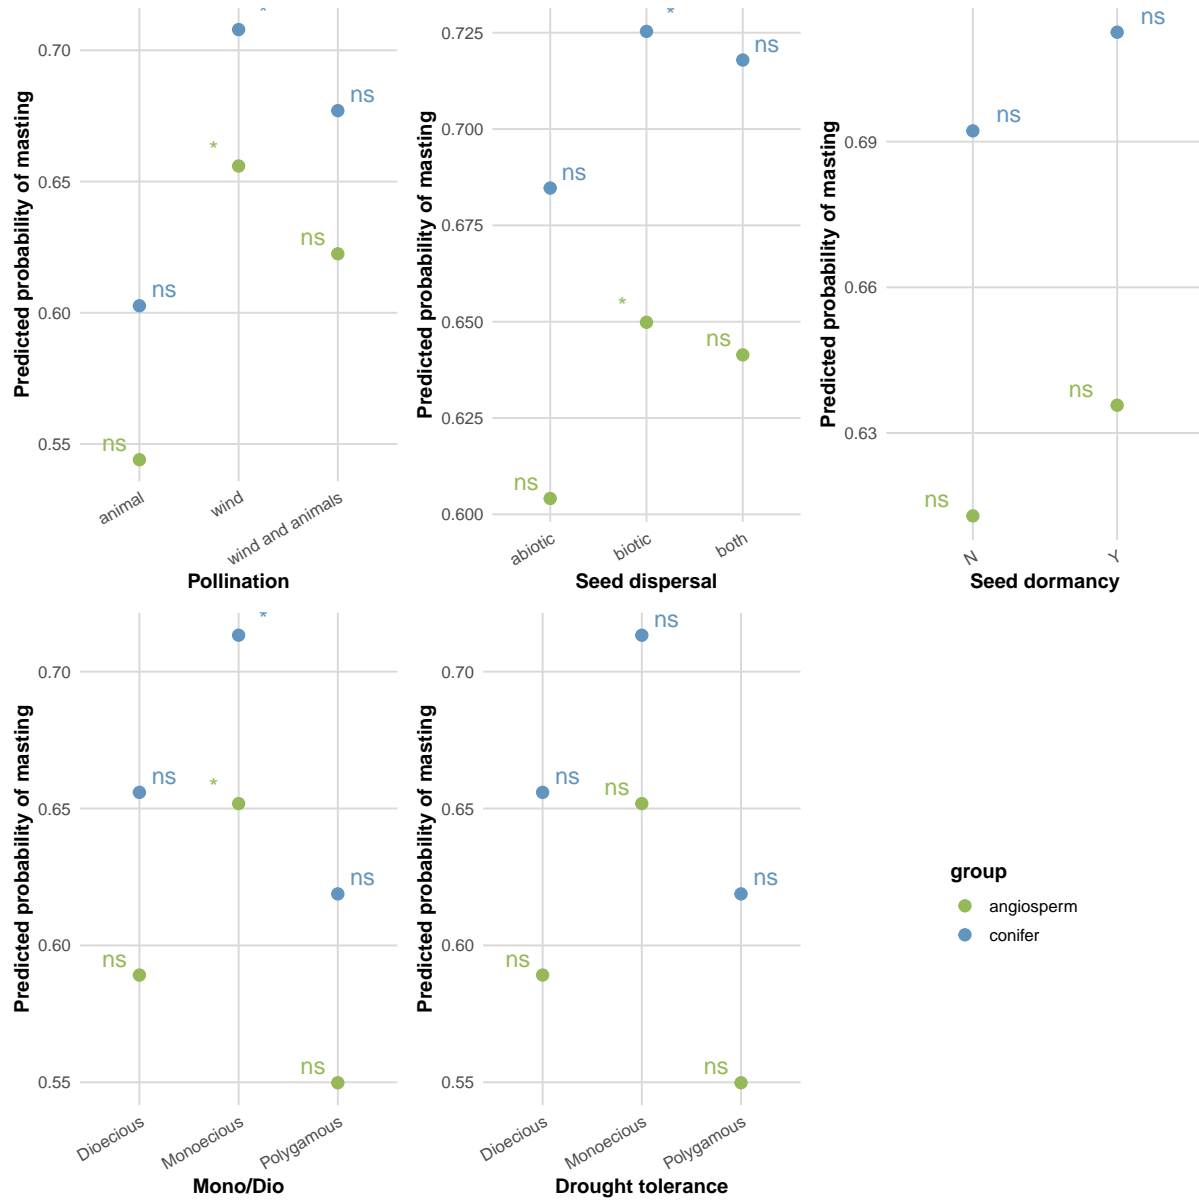

## Results

I ran the phyloglm, including the phylogeny variation.

I also ran the common glm, using conifer and angiosperm as a fixed effect in the model, and here's the results from these models:

For the categorical traits, I calculated the probability (of being a strong masting species) for each level:

For the continuous traits, I just presented the effect sizes, with the star indicating a p-value smaller than 0.05:
